**Keywords:** Sexual dimorphism; Aging; Starvation resistance; Oxidative stress

**Summary statement:** This study demonstrates that *Drosophila* females with altered levels of brain glycogen display a shortened lifespan, increased resistance to starvation, and higher levels of oxidative stress than male flies. Thus, metabolic processes like the glycogen synthesis pathway could influence sex-specific traits in animals.
ABSTRACT

Sexual dimorphism in lifespan, wherein females outlive males, is evident across all animal taxa. The longevity difference between sexes is controlled by multiple physiological processes with complex relationships to one another. In recent years, glycogen, the storage form of glucose, has been shown to cause rapid aging upon forced synthesis in healthy neurons. Glycogen in the form of corpora amylacea in the aging brain is also widely reported. While these studies did suggest a novel role for glycogen in aging, most of them have focused on pooled samples, and have not looked at sex-specific effects, if any. Given the widespread occurrence of sex-biased expression of genes and the underlying physiology, it is important to look at the sex-specific effect of metabolic processes. In the present study, using transgenic fly lines for the human glycogen synthase, we investigated the sex-specific effect of glycogen on stress resistance, fitness, and survival. We demonstrate that Drosophila females with altered levels of glycogen in the brain display a shortened lifespan, increased resistance to starvation, and higher oxidative stress than male flies. The present study thus provides a novel insight into the sex-specific effect of glycogen in survival and aging and how differences in metabolic processes could contribute to sex-specific traits.

INTRODUCTION

One of the long-standing questions in biology is the factors determining the lifespan of a species in a population [1]. Variations in longevity between different species and between members of the same species remain inexplicable [2]. In this respect, sexual dimorphism in lifespan, where females outlive males across species, including humans, is an established concept now, yet the underlying mechanisms are not fully understood [3-5]. Several theories have been proposed to elucidate the variations in lifespan between the two
sexes. One is the “unguarded X hypothesis”, where the heterogametic sex (XY males/ZW females) is expected to have a shorter lifespan as they express deleterious alleles located on the X chromosome. The homogametic sex (XX females), in contrast, might live longer since the effect of the deleterious alleles gets diluted because of the two copies of the X chromosome [6,7]. Another hypothesis that explains the gender-specific difference in the lifespan is “maternal inheritance,” wherein maternally derived mitochondria are thought to function sub-optimally in males, thus adding to the survival advantage in females [6,7]. A difference in the hormone signaling pathways and metabolic circuits has also been accounted for the difference in the lifespan of the two sexes [8]. Few examples include the reduction in the female lifespan post-mating by the male-specific hormone “sex peptide” [9] and the shortening of male survival upon activation of the neuropeptide signaling by a female-specific pheromone [10]. Sex differences in lifespan are also linked with stress-related traits and biochemical factors [11]. According to the “Free Radical Theory of Aging” [12], reactive oxygen species (ROS) are one of the critical determinants of lifespan trade-offs, and a negative correlation exists between lifespan and ROS abundance in particular sex [13]. Studies have indicated that effective mitochondrial function and higher levels of antioxidant enzymes in females compensate for increased ROS levels [5], thus earning a survival benefit over males. Other factors contributing to lifespan variations between males and females are social interaction, sex-specific genetic architecture, aging mechanisms, and fitness parameters [6,14].

At the molecular level, studies on sex-specific lifespan have mostly looked at the difference in the expression levels of essential genes, genes coding for the hormonal and immune response, and genes involved in healthy aging [14,15]. For example, a genetic perturbation in the insulin-signaling pathway increases the survival rate of *Drosophila* females as compared to males [16]. Similarly, chronic treatment
of *Drosophila* with lithium, which acts on the mechanistic target of rapamycin (mTOR) and glycogen synthase kinase-3β (GSK3β), abolishes the female advantage in lifespan with no significant changes in male survival [17]. Dietary restriction, which dramatically enhances lifespan across species, also has a pronounced effect on the female lifespan compared to the males [18]. In this context, glycogen has recently been identified as a potential regulator for the aging process [19,20]. Glycogen, the branched polymer of glucose, acts as an energy reservoir in animals wherein the abundance of glucose in the body activates glycogen synthase (GS), the key enzyme for glycogen synthesis [21]. Interestingly, glycogen in the brain is mostly stored in astrocytes [22], and the glycogen content in the neurons is negligible [23]. This suggests a neuron-specific adaptive response, as abnormal glycogen has been associated with Lafora disease [24] and aberrant levels diminish the overall lifespan in the GS-overexpressing fly lines and mice models [19]. In addition, neuronal GS knockdown promoted healthy aging in *Drosophila* [20]. Moreover, glycogen-mediated accelerated aging is seen in *Caenorhabditis elegans*, where a high sugar diet as a precursor for glycogen results in a shortened lifespan of the worms [25]. The metabolic shift of glycogen synthesis from the astrocytes to the neurons in the aging hippocampus [26] and the presence of glycogen deposits in the form of *corpora amylacea* in the aging brain [27], further establish glycogen as a modifier of the aging process. We, therefore, evaluated the role of brain-specific glycogen changes as a possible factor that can influence the sex-specific lifespan in *Drosophila*. We demonstrate that *Drosophila* females with an imbalance in the level of brain glycogen display a shortened lifespan, increased resistance to starvation, elevated glycogen reserves, and higher oxidative stress than male flies. A shortening in the lifespan of females in the current study is attributed to the altered brain glycogen levels that correspond to the increased oxidative stress in the female flies.
MATERIALS AND METHODS

Materials:

Amyloglucosidase, 2',7'-dichlorodihydrofluorescein-diacetate (DCF-DA), bovine serum albumin was procured from Sigma Aldrich Chemicals India Pvt Ltd. All the other chemicals used in the present investigations were of analytical grade.

Transgenic fly stocks and culture:

UAS-GFP and the pan-neuronal driver line elav-Gal4C155 was a kind gift from Prof. Pradip Sinha (IIT Kanpur, India). Transgenic fly for the wild-type form of hMGS (human Muscle Glycogen Synthase), UAS-hMGS-wt (wild-type form of the hMGS), and UAS-GSRNAi (v35136) was a kind gift from Prof. Joan J. Guinovart (IRB, Barcelona, Spain) and is reported in a previous study [19,20]. Males of the UAS-hMGS-wt and UAS-GSRNAi were crossed with the virgins of elav-Gal4C155 to drive their expression pan-neuronally [28]. UAS-GFP transgene driven with elav-Gal4C155 served as a control.

Flies were maintained at a density of ~100 flies in 40 mL cornmeal–agar medium per 200 mL volume glass bottle at 22±1°C under a constant light-dark cycle with 70%-80% humidity. Following eclosion, flies were aged for 3-4 days and transferred to fresh bottles with media containing live yeast for serial cultures. During experiments, ~20 flies in 5 mL cornmeal–agar medium per 40 mL volume glass vials were employed.

Lifespan analysis:

Freshly eclosed flies were collected, sexed, and transferred (on the same day of eclosion) to glass vials containing 10 mL cornmeal–agar medium. The flies were transferred
to fresh food vials every alternate day for 60 days and thereafter for every 3-5 days depending on media condition. Flies dying during the course of lifespan assessment were not replaced. The survival of flies was monitored daily until all the flies died [29]. For each genotype and sex, five vials were set up with 20 flies in each vial. The mean lifespan of flies was calculated for all the groups.

**Fecundity:**

Freshly eclosed virgin flies were collected, sexed, and transferred (on the same day of eclosion) to separate glass vials containing 10 mL cornmeal–agar medium. To determine fecundity, an unmated male and a virgin female were introduced in the media vial. This pair was transferred to a fresh media vial every day and the eggs laid by females in the preceding day were counted using a stereomicroscope. Fecundity assay was carried out for 12 days; while the dead males were replaced in the course of this assay. A separate group of male flies obtained from the same batch of cultures was maintained in parallel for this purpose [29]. Ten vials were set up for each line. The total number of eggs laid by a female in a day for a given period of time (average daily fecundity) and the fecundity per week/fly were calculated from the data thus collected.

**Development time:**

For assessing the durations of egg-to-adult developmental stages (egg, larva, and pupa), 20 eggs of the same age were placed in a culture vial. These vials were maintained in the vivarium at 22±1°C under a constant 12:12 light-dark cycle with 70%-80% humidity. The time to complete each developmental stage was recorded via regular observation of vials until there was no eclosion of flies for two consecutive days. Five such vials were set up for each
genotype and sex. The time taken (days) by eggs to hatch, the larvae to pupate, or the pupae to eclose was recorded for all the genotypes [30].

**Dry weight:**

Five males or females in 10 batches for each genotype were included in the measurement of dry weight. The flies were transferred to an Eppendorf tube, sacrificed by freezing, dried for 36 h at 60°C, and were weighed [29].

**Starvation resistance:**

Freshly eclosed flies were collected; the males and females were separated and allowed to age for seven days. Ten males and ten females were transferred to separate vials containing non-nutritive media (7 mL of 1% agar only). The vials were plugged with cotton and maintained in a vivarium at 22±1°C under 12:12 light-dark cycles. The flies in these vials were monitored for mortality every 2-3 h until all flies died. The number of flies alive against starvation (in days) between genotypes was monitored until all flies died. Five replicates for each sex and genotype were set up for the assay. The absolute starvation resistance of each group (genotypes and sexes) was calculated as the time till death (in h) for each fly [29].

**Glycogen estimation:**

The glycogen content in the fly head was measured using the protocol described earlier [31] with modifications. Briefly, 20 fly heads per replicate for each genotype and sex were homogenized in 120 µL of 30% KOH solution and boiled at 100°C for 20 minutes. Twenty microliters of this homogenate were used for protein quantification, while the
remaining 100 µL was spotted on a 2 cm x 2 cm Whatman filter paper (#31-ET CHR). The spotted sample was given three consecutive 66% ethanol washes and dried overnight. The dried filter paper was further treated with the enzyme amylglucosidase (0.5 mg/mL in 0.2M sodium acetate buffer, pH 4.8) to release glucose. This free glucose was measured using the glucose colorimetric assay kit (ERBA Diagnostics Mannheim Gmbh Ltd) and was normalized to the protein values and plotted as fold change. Six replicates were taken for each sex and genotype for the assay.

**Glycogen synthase activity:**

Glycogen synthase activity was estimated by modifying Danforth’s spectrophotometric method [32]. Briefly, 50 fly heads per replicate for each genotype and sex were homogenized in 100 µL of phosphate-buffered saline. The homogenate was added to a reaction mixture containing 48mM Tris (pH 8.2), 12.4mM MgCl2, 1mM EDTA, 2.4mM 2-mercaptoethanol, 3.63mM UDPG, 9.7mM glucose 6-phosphate and was incubated for 5 mins at 30°C. The reaction was terminated by boiling the mixture for 5 mins. An increase in absorbance at 340 nm with the addition of enzymes was measured for 5 mins and was normalized to the total protein content.

**Reactive oxygen species measurement:**

Reactive oxygen species were measured using the DCF-DA method [33]. The reaction mixture consisted of Tris-HCl buffer (0.1M, pH 7.4), 100 µL fly head homogenate, and 10 µM DCF-DA. The reaction mixture was incubated for 30 min at room temperature. The breakdown of DCF-DA to the fluorescent product 2’,7’-dichlorofluorescein (DCF) was measured in a microplate reader (Spectrofluorometer) with an excitation wavelength of 488
nm and emission at 525 nm. The values were plotted against the standard DCF graph and expressed as µmol DCF formed/min/mg protein.

**Lipid peroxidation:**

Lipid peroxidation was measured by thiobarbituric acid reactive substance (TBARS) assay [34]. Briefly, the reaction mixture contained 1.5 mL acetic acid (20%), 250 µL fly homogenate, 1.5 mL of TBA (0.8% w/v), and 200 µL sodium lauryl sulphate. The mixture was incubated in a boiling water bath for 45 mins and extracted into 3 mL of 1-butanol. The absorbance was measured at 535 nm and quantified as malondialdehyde equivalents.

**Negative geotactic behavior:**

The inherent behavioral response to climb (negative geotaxis) of flies has been employed to assess their locomotor ability. Ten flies for each genotype and sex with five replicates were employed. Flies were transferred to a vertical column of 25 cm in length and a diameter of 1.5 cm. The flies were gently tapped thrice to the bottom of the column, and the flies that reached the top of the column and those that remained at the bottom were counted separately. The results were expressed as the number of flies that escaped beyond the minimum distance in the 20 s interval [35].

**RNA extraction and real-time PCR:**

Total RNA was isolated from 20-25 fly heads of each genotype using the Trizol reagent according to the manufacturer’s protocol (Life Technologies India). cDNA was synthesized from 1µg of total RNA using random primers and the efficacy of reverse
transcription was verified by amplification of the housekeeping gene *Rpl32* and the transcript level for glycogen synthase was measured using *Drosophila* specific primers (*GlyS*). Real-time PCR was performed using the Luna Universal qPCR master mix (New England BioLabs) and a CFX-96 real-time PCR machine (Bio-Rad Laboratories, India). The primer sequences used for the PCR amplification are *Rpl32*-F ATCGTTACGGATCGAACAA and *Rpl32*-R GACAATCTCCTTGCCTTCT; *GlyS* (*Drosophila*)-F GTTATTGTTTTGTTCGTGTGGC and *GlyS*(*Drosophila*)-R CGAGCGCAATGAGTTGACAG.

**Immunoblotting:**

Western blot analysis for checking the expression of GS in the fly heads was performed as previously described [31]. Briefly, 20 fly heads for each genotype were pooled and lysed in Laemmli buffer and the protein extracted was estimated using the BCA method. Equal amounts of protein were loaded in a 10% SDS-PAGE and transferred to the nitrocellulose membrane (Biorad, 1620112). The membranes were then blocked with 5% nonfat dry milk powder (Biorad, 1706404) in 1X TBST and probed for the anti-GS antibody (Cell Signalling Technology, #3893, 1:1000) overnight [31]. The blot was then probed for the recommended secondary antibodies and the immunoreactive bands were detected with a chemiluminescent detection kit (Supersignal West Pico, Pierce). The signal intensity of γ-tubulin (Sigma Aldrich Chemicals India Pvt Ltd., T6557, 1:10,000) served as the loading control.

**Protein estimation:**

Protein estimation was carried out using the BCA method [36] with bovine serum albumin as a standard.
Statistical analyses:

Statistical analyses of the data were carried out using SPSS software (Version 17.0, SPSS Inc., Chicago). For survival assay, Kaplan-Meier survivorship curves and log-rank (Mantel-Cox) test values were used for calculating significance. Data for all parameters (survival, dry weight, starvation resistance, negative geotaxis assay, and biochemical investigations) were subjected to general linear model analysis using factorial analysis of variance (ANOVA) with sex and genotype groups as fixed factors and individual values as dependent factors. The multiple comparisons were carried out by LSD’s post-hoc test. Statistical significance for real-time analysis was subjected to a two-tailed unpaired t-test using the Graphpad Prism software (Version 7, GraphPad Software Inc., California). P-value <0.05 is considered as significant.

RESULTS

Sex-specific effect of brain glycogen levels on lifespan in Drosophila:

Drosophila, in laboratory conditions, is known to show sex differences in survival, where females live longer than males [6]. Intriguingly, forced glycogen synthesis in the neurons reduces survival in Drosophila [19] and, on the other hand, a neuron-specific GS knockdown extends lifespan [20]. Therefore, we checked whether changes in brain glycogen levels could have a sex-specific effect on the lifespan of the flies. To address this, we have employed two different approaches: (i) pan-neuronal knockdown of GS using RNAi (elav>GSRNAi) and (ii) overexpression of the human wild type GS (elav>hMGS-wt), also used in the previous studies conducted by Duran et. al [19] and Sinadinos et al. [20]. Transgenic lines overexpressing pan-neuronal GFP (the elav>GFP) were used as control [19]. As shown in Figure 1A, the elav>GFP female flies (75.66±2.06 days) survived longer
than the *elav>GFP* males (59.86±4.47 days), in line with the general idea that females outlive males in a population [6]. Contrary to the controls, the *elav>GSRNAi* male flies survived longer (55.34±2.22 days) than the *elav>GSRNAi* females (45.06±2.81 days) (Figure 1B). Similarly, male flies of the genotype *elav>hMGS-wt* (41.62±1.79 days) survived significantly longer as compared with their female counterparts (22.88±1.31 days), although their lifespan was significantly shorter than the *elav>GSRNAi* males (Figure 1B). Unlike females, there was no significant difference between the survival of control (*elav>GFP*, 59.86±4.47 days) males and GS knockdown males (*elav>GSRNAi*, 55.24±2.22 days), although the lifespan of GS overexpression males (*elav>hMGS-wt*, 41.62±1.79 days) was shorter as compared to that of the other two genotypes. The mean lifespan, log-rank, and p values calculated for the above observations are shown in Table 1. Log-rank (Mantel-Cox) test values of cumulative survival of males and females of *elav>GFP, elav>GSRNAi, and elav>hMGS-wt* showed significant differences (Table 1). Significant variations in lifespan between genotypes (F=18.762, P=0.002) and sexes (F=11.793, P=0.011) were observed (Table 2). The interaction between genotype and sex was also significantly different (F=40.722, P=0.0001). The efficiency of GS knockdown and the overexpression of human GS in the two genotypes were confirmed at the transcript and the protein level, respectively (Figure 1C and 1D). Thus, we noted that changes in brain glycogen levels significantly alter the lifespan of *Drosophila* females.

**Effect of brain glycogen alterations on fitness parameters:**

Our observations with the GS knockdown and GS overexpression lines are contrary to the general observations that females live longer than males across species. One possible explanation for this could be the disposable soma theory of aging, wherein a trade-off in energy allocation between reproduction and survival is proposed [37]. Therefore, we looked
at the role of brain glycogen levels on fecundity as a measure of reproduction in flies. Here, we looked at the fecundity for all the lines used in the study i.e., $elav>GFP$, $elav>GSRNAi$, and $elav>hMGS-wt$ (Figure 2A and 2B). The GS knockdown line ($elav>GSRNAi, 9.63\pm1.02$ eggs/day) had no significant difference as compared to the controls ($elav>GFP, 9.78\pm0.51$) in the average number of eggs laid per day (Figure 2A). For the $elav>hMGS-wt$ line, however, the fecundity ($5.22\pm0.91$ eggs/day) was significantly lower as compared to the control group ($elav>GFP, 9.78\pm0.51$) (Figure 2A). The $elav>hMGS-wt$ line showed higher progeny numbers during their early part of the adult stage as compared to the other genotypes, which significantly declined in the later life (Figure 2B).

During the life cycle of Drosophila, the larval stage appears to acquire maximum energy resources [38]. Both larval development and pre-adult survival are crucial for the overall fitness in Drosophila. Therefore, we investigated whether changes in brain glycogen levels could affect development time in the flies. For this, we assessed the overall development time (Figure 2C) across all the genotypes. The $elav>GSRNAi$ flies showed extended development time (12.5±0.00 days) as compared to the $elav>GFP$ (10.6±0.44 days) (Figure 2D), primarily due to the increased time spent in the larva stage (Figure 2C). However, the $elav>hMGS-wt$ line did not show such a marked difference though they seem to spend more time in development as eggs.

In order to explore the possible link between lifespan and body weight, we measured the dry weight of flies belonging to various genotypes. As shown in Table 2, dry weight varied significantly between the genotypes (F=18.275, P=0.0001) and sexes (F=300.0, P=0.0001). Statistical analysis showed significant interactions between genotype × sex for the dry weight (F=24.703, P=0.0001) (Table 2). Females were heavier than males irrespective of the genotypes (Supplementary Figure S1). The dry weight of the control ($elav>GFP$) females was significantly higher ($1.8\pm0x10^{-3}$g) when compared to the GS knockdown ($1.2\pm0x10^{-3}$g)
and GS overexpression (0.9±0 x10⁻³g) females. There was no significant difference in the weight of males across the experimental genotypes [(elav>GFP, 0.44±0x10⁻³ g); (elav>GSRNAi, 0.36±0x10⁻³ g); (elav>hMGS-wt, 0.48±0x10⁻³ g)] (Supplementary Figure S1).

The sex-specific difference in brain glycogen content correlates with female-specific resistance to starvation:

The nutritional challenge is known to affect both survival and reproduction in organisms. In continuation of the two fitness traits studied, we further examined the response of prolonged starvation on flies with variable levels of brain glycogen, given that glycogen serves as an energy reserve. For this, we measured resistance to starvation for both knockdown (elav>GSRNAi) and overexpressed (elav>hMGS-wt) models of GS and in both the sexes (Figure 3A). There was a significant variation in starvation resistance between genotypes (F=4.040, P=0.019) and sexes (F=5.786, P=0.017) as well as the interaction between genotype x sex was found significant (F=13.809, P=0.0001) (Table 2). In the control flies, starvation resistance was higher in males than females, whereas in GS transgenic flies, females displayed higher starvation resistance than males. Based on our results, starvation resistance appears to negatively correlate with the lifespan, wherein short-lived female flies of elav>GSRNAi and elav>hMGS-wt were resilient to starvation stress as compared to their long-lived male sex.

Moreover, the inverse relationship in starvation resistance observed between the control and GS transgenic flies indicated that changes in brain glycogen levels have a pronounced sex-specific effect on physiology. We hypothesized that a difference in glycogen content between males and females might underlie this effect. Therefore, we wanted to check...
whether females store a higher amount of glycogen compared to their male counterparts. For this, we estimated the GS enzyme activity and the glycogen levels in the fly heads of all genotypes at one week of age (Figure 3B and 3C). Measurements of both glycogen and GS activity were carried out in a sex-specific manner. One-way ANOVA was used to calculate the significance across genotypes. The elav>GFP (control) flies had a negligible and non-significant difference in their GS activity and glycogen values between sexes (Figure 3B and 3C). On the other hand, in the other two genotypes (elav>GSRNAi and elav>hMGS-wt), the females had considerably higher glycogen reserves when compared to males (Figure 3C), though there was no significant difference in the GS enzyme activity between sexes (Figure 3B). As expected, the GS activity and the glycogen content in both the sexes were lowest in the GS knockdown flies (elav>GSRNAi) and the highest in the flies overexpressing the wild-type form of GS (elav>hMGS-wt) as compared to the controls (elav>GFP). Statistical analysis revealed the significant interactions for glycogen level between genotypes (F=468.05, P=0.0001), sexes (F=144.06, P=0.0001) and genotype x sex (F=1.808, P=0.0001) (Table 2). Nevertheless, the interactions for GS activity between genotypes was significant (F=1457.66, P=0.0001), but non-significant between sexes (F=0.169, P=0.687) and genotype x sex (F=3.754, P=0.127). Thus, higher starvation resistance in the females of both GS-knockdown and for the GS-overexpressed lines correlates with their altered glycogen reserves. Therefore, female flies with altered brain glycogen (either low or high) show a greater defense against starvation throughout their life when compared to males.

**Effect of brain glycogen on oxidative stress and lifespan in females:**

Glycogen accumulation has been observed in the neurons subjected to various stressors, including oxidative stress [23,30,39,40]. Moreover, the lifespan of organisms is inversely correlated with the increased oxidative damage and ROS levels [13]. Given the
female-specific decrease in lifespan and increased glycogen reserves and the established correlation of glycogen buildup in the neurons under stress conditions, we hypothesized that a shorter lifespan and/or decreased survival observed in the females might result from higher oxidative stress in the female flies. Thus, we wanted to measure the possible sex-specific difference in the oxidative stress levels in flies of all genotypes used in the present study. For this, we used the DCFDA method [33] to check the difference in the relative levels of ROS and TBARS assay [34] to measure lipid peroxidation levels, as oxidative stress markers, between males and females (Figure 4A and 4B). Notably, the oxidative stress level indeed differed between males and females of the \( \text{elav} > \text{GSRNAi} \) and \( \text{elav} > \text{hMGS-wt} \) genotypes. In the DCFDA estimation, females were found to have a significantly higher amount of ROS levels as compared to males in the GS knockdown \( (\text{elav} > \text{GSRNAi}) \) and overexpression \( (\text{elav} > \text{hMGS-wt}) \) states (Figure 4A). This difference was absent in the control \( \text{elav} > \text{GFP} \) males and females. There was a significant variation in ROS levels between genotypes \( (F=18.557, P=0.0001) \) and sexes \( (F=49.738, P=0.0001) \) as well as the interaction between genotype x sex was found significant \( (F=13.268, P=0.002) \) (Table 2). In line with the ROS levels, lipid peroxidation in the TBARS assay was found to be higher in the \( \text{elav} > \text{GSRNAi} \) and \( \text{elav} > \text{hMGS-wt} \) females with increased brain glycogen levels compared to males (Figure 4B). Contrastingly, in control flies, males showed higher levels of MDA compared to females. There was a significant variation in lipid peroxidation between genotypes \( (F=51.024, P=0.0001) \) and sexes \( (F=117.04, P=0.0001) \) as well as the interaction between genotype x sex was found significant \( (F=82.245, P=0.0001) \) (Table 2). We attribute the marked increase in oxidative stress and altered brain glycogen variations to the shortening of lifespan in females compared to the male flies.
**Effect of brain glycogen on locomotor activity:**

Negative geotaxis is used as an index of locomotor behavior in flies [35]. The loss or impairment in climbing ability is used as a readout of motor changes. Thus, to determine whether or not the brain glycogen level will affect motor behavior, we monitored the locomotory performance of flies representing various genotypes used in the study (Supplementary Figure S2). We observed reduced locomotor activity in GS-overexpressed flies \( (elav>hMGS-wt) \) when compared to other genotypes. Statistical analysis showed a significant variation between genotypes \( (F=9.400, P=0.003) \), whereas interactions between sexes \( (F=2.429, P=0.141) \) and genotype x sex \( (F=0.718, P=0.505) \) were non-significant (Table 2).

**DISCUSSION**

Although a correlation between glycogen levels and lifespan has been established in fly and mouse models where a lower GS activity enhances lifespan \( (elav\textgreater GSRNAi) \), and a higher enzyme activity resulted in a shorter lifespan \( (elav\textgreater hMGS-wt) \) [19,20], the sex-specific effect of glycogen alterations in survival and other fitness traits has not been investigated yet. This study demonstrated that female flies with altered brain glycogen levels exhibit a shortened lifespan and higher sensitivity to oxidative stress than males. Further, altered glycogen levels had a positive effect on starvation resistance in female flies as compared to their male counterparts. Our findings offer a novel concept on brain glycogen-mediated control of sex-specific traits, which is beyond the well-known function of glycogen being the energy pool of the cell.
Notwithstanding the concept of the females being the longer-lived sex in *Drosophila melanogaster* [6,11], we observed males living longer than females in transgenic flies having an altered brain-specific GS activity. Differential regulation of GS, or GS-regulated pathways, in the two sexes could possibly be one of the possible reasons that underlie this response where the activity of GS might be optimized in females in comparison to males. Thus, an imbalance in the GS activity and/or glycogen levels abolished the female advantage in survival over males in our study. Such differential expression of the transcriptome is indeed reported in various models wherein the expression of certain genes is antagonistically selected in one sex, and their altered expression could be deleterious for the other [41-43]. However, it is intriguing to note here that the partial knockdown and the overexpression of GS showed a similar trend for some of the phenotypes analyzed. Indeed, either the loss or gain of some of the neuronal proteins involved in homeostatic processes are known to result in similar neuronal defects [44-46]. We did not find a difference in the lifespan between the males of control (*elav>*GFP) and GS knockdown (*elav>*GSRNAi), however, the male lifespan decreased with GS overexpression (*elav>*hMGS-wt). As the pattern for male lifespan was not converse or parallel in the two genetic perturbations as compared to the control, we reasoned that altered brain glycogen does not influence male lifespan and the specific decrease of male lifespan in the GS overexpression line is because of the fact that glycogen accumulation leads to premature aging in flies as shown previously [19,20].

In our study, the fecundity of the flies remained unaltered in the GS knockdown line (*elav>*GSRNAi) but reduced in GS overexpressed line (*elav>*hMGS-wt), suggesting a lack of significant role in survival. However, we correlate the uncompromised fecundity with a shorter lifespan of females as demonstrated by Zwaan et al. [47]. Reduction in the fecundity of *elav>*hMGS-wt flies could be attributed to early reproductive benefits, wherein these flies showed a higher fecundity rate during the initial days of lifespan that eventually plateaued. In
addition, we observed an extension in the overall development time in the GS transgenic flies indicating a prolonged feeding time in these genotypes, which might help in enhanced adult fitness as shown earlier [48]. The longer feeding time during development might help in allocating resources for increased weight, especially in female flies. Increased body weight has been correlated with a longer lifespan [38]. Although control flies showed a positive correlation between body weight and longer lifespan in our study, we found a negative relationship in experimental groups.

The ability to survive food shortage is an adult fitness trait and starvation resistance is specifically reported in *Drosophila* as an adaptive trait orchestrated by many genes [49]. Emerging reports describe that women live longer than men during severe famine [50]. In agreement with previous studies, female flies of the GS transgenic lines displayed an increased starvation resistance as compared to the males and this might correlate to the increase in the glycogen content in GS transgenic females. However, the *elav>*hMGS-wt males displaying decreased starvation resistance and the higher glycogen content suggests that glycogen might not be the primary reservoir of energy in male flies during starvation. A difference in glycogen utilization upon starvation between genders is indeed reported in the literature [51,52]. Recently, Yamada et al. [53] have also shown higher starvation resistance in female GS-null mutants compared to male flies. Glycogen here can act as an energy pool for females under starvation similar to our observation. A decrease in the brain glycogen content upon starvation and a compromised starvation resistance were reported in these GS mutants with fluctuating dietary carbon [53], further confirming that glycogen reserves in the brain facilitate starvation stress. Furthermore, knocking down GS is shown to extend lifespan in *C. elegans*, flies, and mice [18,19,54]. In line with the literature, our results also reveal that lower GS activity enhances lifespan (*elav>*GSRNAi), whereas higher enzyme activity results in a shorter lifespan (*elav>*hMGS-wt). Brain glycogen metabolism is also suggested to be
sexually dimorphic [55], as gonadal steroids are known to affect brain and body bioenergetics (viz., glucose uptake, mitochondrial oxidative phosphorylation, oxidative stress, etc.) [56]. This could underlie the enhanced storage of glycogen in females as compared to males observed in the present study. Another fitness index of the present study, the negative geotactic behavior which mostly depends on age, sex, and oxidative stress [57], did not show a prominent sex-specific change in our study, suggesting a lack of glycogen-mediated influence on gender-specific locomotion.

Oxidative damage to the biomolecules contributes to the sex-specific shortening of lifespan, which could be due to the malfunctioning of the mitochondria [6] or increased metabolism [58]. Oxidative stress remains one of the key factors in aging and age-related neurodegenerative disorders like Alzheimer’s and Parkinson’s diseases. Furthermore, lipid peroxidation is regarded as the major process causing oxidative damage, and age-associated sex-specific elevation in lipid peroxidation is also reported [59]. Under normal physiological conditions, females are less susceptible to oxidative stress due to lower levels of NADPH-oxidases, higher antioxidant potential, and female-specific hormones like estrogen (reviewed in [60]). In contrast to previous studies, GS transgenic female flies showed higher ROS and MDA levels compared to males. In agreement with earlier studies, the higher ROS/MDA level is associated with decreased survival. Additional work demonstrating antioxidant defenses (superoxide dismutase and catalase) in both sexes may provide a clear picture to substantiate the difference in ROS homeostasis and its role in survival. Nonetheless, our results indicate that brain glycogen alterations might influence the ROS levels possibly by affecting mitochondrial function. Similarly, the glycogen content in the brain may also modify the neuronal circuitry involved in sex-specific hormonal regulation. For example, estrogen lengthens the lifespan in females because it possesses antioxidant and anti-inflammatory properties [61,62]. This property of estrogen also extends to the brain, as it has
a neuroprotective effect, and loss of estrogen increases ROS levels and accelerates aging in diseases like Alzheimer’s disease [63]. Malfunctioning the hormonal axis due to a change in brain glycogen ratios can impact the hormonal profile, increasing the pro-oxidant levels, particularly in the female flies. A concurrent role between glycogen and pro-oxidants for regulating lifespan differences is also evident in our study, wherein flies with low pro-oxidants and glycogen survived longer than flies with higher pro-oxidants and glycogen levels. Taken together, we propose that these fitness traits act synergistically to help the organism survive better against the odds and a direct correlation exists between brain glycogen alterations, specifically in the females, and pathways that regulate adult fitness traits. Thus, glycogen homeostasis in the fly brain appears to be essential for maintaining female physiology and normal health span.

ACKNOWLEDGMENTS

The authors thank Professor Joan J. Guinovart (IRB Barcelona, Spain) for the GS fly lines and Professor Pradip Sinha (IIT Kanpur) for extending his Drosophila facility for the study.
