The Metaphase Spindle in the Spermatogenetic Mitoses of Forficula Auricularia.

C. F. U. Meek, M.Sc., F.L.S., F.Z.S.

With Plate 17.

Introduction.

In a paper published at the beginning of this year I have shown that only one generalisation has been established concerning the mitotic spindle, viz. that it is not a figure formed entirely by the action of forces at its poles. The arguments put forward by Hartog in support of his "mitokinetic" force prove that, if this generalisation is denied, the spindle can be formed by no known forces. Gallardo and Rhumbler have been compelled to accept this proposition; and all early theories either admit it, or are disproved because they do not admit it.

I pointed out that in the circumstances we must collect data, and not attempt to explain mitosis until other generalisations have been established. Our knowledge of the morphological features of the cell and of the chemical nature of its component parts is rudimentary; and, since we know nothing concerning the forces working in mitosis and concerning the changes undergone by the mechanism in the course of evolution, speculation upon the subject is at present likely to prove abortive. The work of each decade has shown more and more that the cell is a highly complex entity; and the results of future research may prove it to be even more complex than we now suspect. Recently several writers upon both chromosomes and the achromatic portions of the cell have suggested

that chemistry will provide the solution of problems that so far we have failed to solve. That eventually we must hand over to others problems that are found to lie beyond the scope of our investigations cannot be denied; but, until we have amassed data such that we can answer every question concerning the morphology and movements of structures that are visible in the cell, we are not justified in relying upon other branches of science for more than co-operation in our endeavour to explain these phenomena.

In a paper upon chromosome dimensions published last year I was able to show that increasing somatic complexity of the organism is accompanied by increase of the volume of chromatin in its germ-cell, and that the diameter of chromosomes becomes greater as we pass from low to higher phyla of the animal kingdom. I now propose to carry out similar investigations upon the phenomenon known as the mitotic spindle, and shall try to discover whether at a given moment in a given mitosis the length is constant or arbitrary; if it is found to be constant, we must determine the relationships between lengths at corresponding stages of successive mitoses, and must ask if these relationships are connected with those of other phenomena.

The stage that is most easy to identify in mitosis is the conclusion of the metaphase, when the chromosomes have undergone complete fission, and the daughter-rods, apposed to one another, are ready to move towards the two poles. I shall therefore make consideration of this stage the basis of my research, and shall determine the length of the spindle by measuring the distance between the centrosomes. I have chosen Forficula for these investigations, because the chromosomes are either spheres or very short rods; it is accordingly easy to recognise the moment at the conclusion of the metaphase when constriction is completed. Since the two centrosomes can seldom be brought into focus simultaneously at the highest magnifications, figures in which the spindle length is to be measured will be represented in the plates by two drawings: the first will show a lateral view of the equatorial

plate at a magnification such that no doubt can exist concerning the stage of mitosis; the second will show a lateral view of the two centrosomes at a lower magnification, from which the length of the spindle must be deduced.

It is unlikely that these measurements will lead directly to an explanation of spindle formation; but they may suggest some further generalisation, which will bring us one step nearer to the solution of this problem.

Material and Methods.

The material was collected in July, and preserved in either Flemming's strong chromo-aceto-osmic acid fluid or the platino-aceto-osmic acid solution of Hermann. In an earlier paper I recommended the latter; but for these studies, in which extreme transparency of the cytoplasm is essential, the former has undoubtedly given the better results.

The testes were not dissected out until required for embedding; but the integument of the back was slit open to ensure immediate access of the fixative, in which the material remained for twenty-four or forty-eight hours. It was then washed in running water for twenty-four hours, and passed successively through 30 per cent., 50 per cent. and 70 per cent. aqueous solutions of alcohol, remaining for four hours in each of the two first-named and for eight hours in the last. It was then stored in a solution of 80 per cent. alcohol.

Later, the testes were placed in a 90 per cent. aqueous solution of alcohol for twenty-four hours, and then passed through a 95 per cent. solution, absolute alcohol, and xylol; after which they were embedded in paraffin having a melting-point of 52° C. Sections were cut 8 μ thick with an ordinary Cambridge rocking microtome, and were stained on the slide. The mordant used was an aqueous solution of iron alum, in which the sections remained for six hours; they were then stained for fifteen hours in Heidenhain's iron-hæmatoxylin, and the excess of colour was later washed out

with a weak solution of the iron-alum. When a plasma stain was used in conjunction with the iron hæmatoxylin, the slides were first stained for ten minutes in eosin, care being taken that the colour was not destroyed by the strong solutions of alcohol in which they were later placed.

The preparations were studied by means of a Zeiss apochromatic oil-immersion objective of 2 mm. focus and N. A. 1·30, in conjunction with compensating oculars, Nos. 6, 12 and 18. When necessary, resolution was facilitated by interposing a Gifford screen. The source of illumination was an inverted incandescent gas-lamp, used in combination with the holoscopic oil-immersion substage condenser made by Messrs. Watson & Sons, of London. All drawings were made with a large Abbe camera lucida, and the magnification was estimated by means of a stage micrometer, graduated to read one hundredth of a millimetre. Whenever drawings were about to be made, both microscope platform and drawing table were carefully levelled; and error due to foreshortening was obviated by making drawings only of those spindles whose major axes lay exactly at right angles to the microscopic line of vision, i. e. whose centrosomes could be focussed simultaneously. Moreover, in order to minimise error due to draughtsmanship, the centrosomes of each spindle were drawn upon several occasions, and at least one hundred times in all.

The Length of the Mitotic Spindle at the Conclusion of the Secondary Spermatocyte Metaphase.

Figs. 1 to 5, Pl. 17, are drawings of polar views of the secondary spermatocyte metaphase, and all the chromosomes are shown. Those chromosomes that are short rods lie on the spindle in a manner such that their major axes are at right angles to the equatorial plane; consequently all must appear to be spherical in a perfectly polar view. The complex is composed of a single ring of ten chromosomes with two lying within it, or of a ring of nine chromosomes with three within it; the former arrangement is seen in

immediately above it. Constriction of the chromosomes is in progress in fig. 11, and is completed in fig. 12; in figs. 13, 14 and 15 the daughter-chromosomes appear to be moving further and further apart. The centrosomes of these cells are represented by figs. 54 to 58 respectively; and these drawings, made at a magnification of 889 diameters, are respectively identical with those given in figs. 49 to 53. These measurements, which have been made from cells belonging to the testes of a single specimen, can leave little doubt that the length of the spindle at the conclusion of the metaphase is a constant for this cell generation of the individual.

We must now ask if this constant may be assumed for all members of the species. Figs. 16 to 20, Pl. 17, are drawings of the equatorial plate of five cells in the testes of a second specimen, and each is seen to correspond exactly with the two drawings placed immediately above it. Fig. 16 shows a late metaphase, which is found to be concluded in fig. 17; figs. 18, 19 and 20 represent successive stages of the anaphase. Figs. 59 to 63, Pl. 17, show the centrosomes of these cells, drawn at a magnification of 889 diameters. And, since these drawings are respectively identical with figs. 49 to 53 and 54 to 58, we have reason for believing that the spindle length is a constant at the conclusion of the secondary spermatocyte metaphase in all specimens of F. auricularia.

The Length of the Mitotic Spindle at the Conclusion of the Primary Spermatocyte Metaphase.

Having discovered a probable constant for the spindle of the secondary spermatocyte metaphase, we will consider the primary spermatocyte mitosis. Figs. 21 to 24 represent polar views of the metaphase, and all the chromosomes are shown; fig. 25 is a drawing of the slightly later stage when the daughter-chromosomes have begun to move towards the poles. As in the secondary spermatocyte metaphase, the major axes of those chromosomes that are short rods are at right angles to the

equatorial plane. The complex again appears to be composed of a ring of nine or ten chromosomes with three or two respectively lying within it; figs. 21, 22 and 25 represent the latter arrangement, and figs. 23 and 24 the former. I have again failed to discover which arrangement is normal.

Figs. 26 to 29, Pl. 17, are drawings of the equatorial plate of four cells of which the centrosomes, represented at a magnification of 889 diameters, are given in figs. 64 to 67, Pl. 17. The drawings on Pl. 17 clearly show that constriction of the tetrads has been completed, and that the daughter-chromosomes are ready to move apart. The length of the spindle, found from figs. 64 to 67, is without exception 10·4 μ; and, since the stage of the cells depicted is that with which we are dealing, we have reason for supposing that a constant exists also for this mitosis. The uneven pair of heterochromosomes is marked x in those cells in which it is visible.

Let us now measure the spindle length in four more cells in order to test the validity of this supposition. Figs. 30 to 33, Pl. 17, are drawings of the equatorial plate in cells of which the centrosomes are respectively represented by figs. 68 to 71, Pl. 17. Fig. 30 shows the constriction of the tetrads in progress; fig. 31 shows this constriction completed, as in figs. 26 to 29; and figs. 32 and 33 show the first divergence of the daughter-dyads. The distances between the poles of these cells, found from figs. 68 to 71, are respectively 10·2, 10·4, 10·7 and 10·9 μ, and therefore accord with the length of the spindle found for figs. 26 to 29. We must suppose that fig. 30 would have become identical with fig. 31, if fixation had not occurred until its centrosomes were 10·4 μ apart; and we must likewise suppose that the equatorial plates shown in figs. 32 and 33 passed through the stage shown in fig. 31, when their spindles were of the same length as that of the last named. In the circumstances I shall assume that the length of the spindle at the conclusion of the primary spermatocyte metaphase is a constant for this species.

I have found measurements in this metaphase more difficult to make than in that of the secondary spermatocyte; for

constrict; in this case the distance between the centrosomes is found from fig. 73 to be 6·9 μ. Fig. 41 represents the equatorial plate at the conclusion of the metaphase, and the dyads are seen to have become resolved into pairs of univalent spheres or rods, which are ready to move towards the poles. Fig. 74 shows the centrosomes of this cell, and the length of the spindle, estimated from the known magnification, is 7·1 μ. Figs. 42 and 43 are drawings of the equatorial plate in the earliest anaphase, and the daughter-chromosomes are seen to be moving apart. The centrosomes of these cells are represented in figs. 75 and 76 respectively, and their distances apart are 7·3 and 7·6 μ. It is difficult not to believe that figs. 39 and 40 would have resembled fig. 41, if fixation had not taken place until their spindle-poles were 7·1 μ apart; it is also difficult not to believe that figs. 42 and 43 were identical with fig. 41 at the moment when this was the distance between their poles.

Let us now turn to cells of this generation in the testes of another specimen. Fig. 44 shows the equatorial plate before constriction of the chromosomes has begun; figs. 45 and 46 show the equatorial plate while constriction is in progress; and figs. 47 and 48 show it at the conclusion of the metaphase, when constriction is completed. The centrosomes of these five cells are represented in figs. 77 to 81 respectively, and their distances apart accord with those already observed for this mitosis; for the length of the spindle is found to be 6·6 μ in fig. 44, 6·9 μ in figs. 45 and 46, and 7·1 μ in figs. 47 and 48. In the circumstances I shall assume that the length of the spindle at the conclusion of the metaphase is a constant for the secondary spermatogonial mitosis, as we have already assumed it to be for the primary and secondary spermatocyte.

The Ratios between the Lengths of the Mitotic Spindle at the Conclusion of the Spermatogonial and Spermatocyte Metaphases.

Having found that spindle lengths are probably constant at the conclusion of the metaphase of these mitoses, we

anaphase, i. e. at the moment when the daughter-chromosomes have begun to move apart, appears to be a constant for each spermatogenetic mitosis of the species. The lengths found are 7·3, 10·7 and 8·3 μ for the secondary spermatogonia and primary and secondary spermatocytes respectively.

(4) The ratio between the lengths of the mitotic spindle at the conclusion of the primary and secondary spermatocyte metaphases is almost identical with the ratio between the radii of two spheres of which the volume of one is equal to twice that of the other; and the volume of the primary spermatocyte cell must be equal to twice that of the secondary spermatocyte at this stage, because no growth or resting stage intervenes.

(5) The ratio between the lengths of the mitotic spindle at the conclusion of the primary spermatocyte and secondary spermatogonial metaphases is almost identical with the ratio between the radii of two spheres of which the volume of one is equal to three times that of the other. The initial volume of the primary spermatocyte cell must be half that of the secondary spermatogonium, because the latter divides to form two daughter primary spermatocytes; but the large size of the last-named, observed at the close of the growth period, does not refute the suggestion that the initial volume is increased six-fold during this period.

(6) If coincidence is not responsible for the apparent connection between the ratios mentioned above, correlation is established between the cell volume and length of spindle in the spermatogenetic metaphases of this species.
